RESUMEN
Se utiliza la ecuación de advección-difusión para describir la dispersión de contaminantes en un área limitada. Se sugieren métodos para prevenir niveles peligrosos de contaminantes en zonas de importancia ecológica. Los métodos se basan en el control de las tasas de emisión de las fuentes y utilizan estimaciones directas y adjuntas de la concentración media de la contaminación en las zonas. Mientras que las estimaciones directas utilizan las soluciones del problema de transporte de un contaminante y permiten llevar a cabo el estudio de la situación ecológica en todo el dominio, las estimaciones adjuntas permiten la obtención de información sólo en las zonas seleccionadas del dominio. Las estimaciones adjuntas se obtienen por medio de soluciones al problema adjunto y dependen explícitamente de las posiciones de las fuentes y sus tasas de emisión, así como de la distribución inicial del contaminante en la región. En cada estimación, la solución al problema adjunto sirve como la función de influencia que muestra la contribución cuantitativa de cada fuente a la contaminación de la zona correspondiente. Por lo tanto, las estimaciones adjuntas constituyen una herramienta muy eficaz en el estudio de la respuesta del modelo a los cambios en las tasas de emisión y las condiciones iniciales, así como en el desarrollo de estrategias de control. Se sugieren varias estrategias de control óptimas y suficientes (no óptimas). Cada estrategia consiste en reducir las tasas de emisión de las fuentes, y define la intensidad máxima admisible (en caso de control óptimo) o una intensidad suficiente (en caso de control suficiente) de cada fuente, para evitar violaciones de las normas sanitarias. En el diseño de dichos criterios se han tomado en cuenta las condiciones dinámicas de la atmósfera o el océano (mar), es decir, los procesos de propagación, dispersión y transformación de contaminantes, así como el número de fuentes que se controlan, sus ubicaciones y las normas sanitarias. Los métodos de control desarrollados se ilustran con ejemplos sencillos, utilizando los modelos de dispersión bidimensionales. Sin embargo, dichos métodos también pueden aplicarse a los modelos tridimensionales. Como ejemplo, en la última parte del artículo, se considera un modelo tridimensional de la dispersión. Además, para ampliar el ámbito de aplicación de los métodos de control de la intensidad de las fuentes, las estrategias de control óptimo se aplican a una fuente que emite una sustancia química para limpiar sistemas acuáticos contaminados con biopelículas (remediación) o petróleo (biorremediación).

ABSTRACT
The advection-diffusion equation is used for describing the dispersion of pollutants in a limited area. Methods for preventing dangerous levels of pollutants in ecologically important zones are suggested. The methods are based on the control of emission rates of sources and use the direct and adjoint estimates of the average pollution concentration in the zones. While the direct estimates use solutions of the pollution transport problem and permit to study the ecological situation in the whole domain, the adjoint estimates allow getting information only in the selected zones of the domain. The adjoint estimates are obtained with solutions to the adjoint problem and depend explicitly on the positions of the sources and their emission rates, and on the initial distribution of pollutants in the region. In each such estimate, the adjoint problem solution serves as the influence function that shows the quantitative contribution of every source into the pollution of the corresponding zone. This makes the adjoint estimates very efficient tools in the study of the model response to changes in emission rates and initial conditions, as well as in the development of control strategies. Both
non-optimal (sufficient) and optimal control strategies are suggested. Each strategy consists in reducing the emission rates of sources, and defines maximum allowable intensity (in case of optimal control), or sufficient intensity (in case of sufficient control) of each source to avoid violations of hygiene standards. Such criteria are designed taking into account dynamic conditions in the atmosphere or ocean (sea), that is, the processes of propagation, dispersion and transformation of pollutants, as well as the number of sources to control, their locations and the sanitary norms. The control methods developed are illustrated with simple examples using two-dimensional dispersion models. However, these methods can also be applied to three-dimensional models. As an example, in the last part of the article, a three-dimensional model of dispersion is considered. In addition, to expand the scope of application of the methods of control of the intensity of sources, the optimal control strategies are applied to a source that emits a chemical substance to clean aquatic systems contaminated with biofilms (remediation) or oil (bioremediation).

Keywords: Dispersion model, adjoint model, control of emission rates of sources.

1. Introduction

The main reasons for pollution in any environment are a huge global population and a modern lifestyle that demands and consumes large amounts of goods and services. For example, due to this demand, which has presented a steady increase in recent decades, large volumes of raw materials and fossil fuels are transformed to various pollutants released into the atmosphere (Domenech, 1999; López-Coronado and Guerrero-Nuño, 2004). The environment has mechanisms to dilute and assimilate these pollutants and returning them to nature (Seinfeld, 1992); however, during the last century, anthropogenic activities emit into the atmosphere at short intervals, such large volumes of substances in confined areas (cities, industrial parks, etc.) that the mechanisms of assimilation do not have time to recycle the excess of chemicals and to clean the atmosphere. The result is the accumulation of different primary pollutants, leading to the generation of secondary species (Seinfeld, 1992; Wark et al., 1998; Marinescu et al., 2008), which form a mixture that produces a variety of damages to humans and ecosystems (Caselli, 1996).

A pollutant, depending on its concentration and toxicity, causes various health problems (Kawada, 1984), from respiratory discomfort in healthy people to the increase in mortality among vulnerable populations (cardiac patients, children, elderly persons, etc.). Anyway, pollution is a factor that diminishes the quality of life of human beings. Unfortunately, the impact of mixing of pollutants in ecosystems can be not only local, as in the case of photochemical smog (Bravo et al., 1991), but also regional, as in the acid precipitation (Beilke and Elshout, 1983; Rodhe et al., 1981), or global, as the phenomenon of destruction of the ozone layer and global climate change (Rivera, 1999; Rubinstein, 2001; Karnosky et al., 2003).

Consequently, it is important to design methods for controlling emissions and reducing the concentration of hazardous substances to acceptable health standards (Programma di Ricerca, 2004; Pérez Sesma, 2012). To this end, mathematical models of pollutant dispersion as well as their adjoint models are used (Marchuk and Skiba, 1976; Marchuk, 1986; Panos and Seinfeld, 1986; Skiba, 1997; Davydova-Belitskaya et al., 1999, 2001; Skiba and Parra-Guevara 2000; Parra-Guevara and Skiba 2003, 2006, 2011; Liu et al., 2004, 2005, 2007; Kowalok, 2004; Moreira et al., 2005, 2010; Hinze et al., 2009; Mendoza and García, 2009).

The pollutant dispersion models permit us to carry out the computer-simulation of concentrations of various primary and secondary pollutants in a region (Skiba, 1993, 1997; Skiba and Parra-Guevara, 2000, 2007, 2011; Hussain, 2007; Dorado and Moreira, 2009; Hongfei, 2010; Hongfei and Hongxing, 2011; Parra-Guevara et al., 2010; Fu and Rui, 2011, 2012; Li et al., 2012a), and thereby identify the domains where the emissions have a greater impact. The method allows identifying the main sources of excessive pollution in a selected zone (residential area, park, forest, etc.). In particular, it can be used for the evaluation of pollution levels due to oil spills (Skiba, 1996, 1999; Skiba and Parra-Guevara, 1999; Dang et al., 2012), or to vehicular emissions along the main roads (Skiba and Davydova-Belitskaya, 2003; Chiou and Chen, 2010; Li et al., 2012b; Shafiq and Iqbal, 2012); for estimating parameters which describe the source location and strength (Keats et al., 2007a, b); for the detection of industrial plants which violate the emission rates, prescribed by some control strategy (Skiba, 2003); for the reconstruction of an unknown number of contaminant
Control of emission rates

2. Pollution dispersion model in a limited area

To simplify the study, we will often consider a two-dimensional (vertically averaged) problem of pollutant dispersion. The three-dimensional problem is applied in this work only in the numerical experiment related to the remediation of contaminated aquatic systems. In addition, we will always consider the process of dispersion of contaminants separately from the fluid dynamics problem, supposing that the transport velocity and other dynamic parameters of the problem are known from observations or some dynamic model.

2.1 Boundary and initial conditions

Suppose that in a two-dimensional limited domain $D$ with boundary $S$, there are $N$ industrial factories located at points $r_i = (x_i, y_i)$, $i = 1, 2, ..., N$. Let $\phi(r, t)$ be a concentration of a pollutant in point $r = (x, y)$ and moment $t > 0$. To study the propagation of the contaminant in time interval $(0, T)$, we consider in the domain $D$ and time interval $(0, T)$ the advection-diffusion-reaction equation

$$\frac{\partial}{\partial t} \phi + \text{div}(U \phi) + \sigma \phi - \text{div}(\mu \nabla \phi) = f(r, t)$$

(1)

where $U(r, t) = \{u(r, t), v(r, t)\}$ is the wind velocity vector, $\sigma(r, t) > 0$ characterizes the speed of exponential decay of $\phi(r, t)$ due to various physical and chemical processes, $\mu(r, t) > 0$ is the turbulent diffusion coefficient, $\nabla$ is the 2D gradient,

$$f(r, t) = \sum_{i=1}^{N} Q_i(t) \delta(r - r_i),$$

(2)

$Q_i(t)$ is the emission rate of the $i$th industry, and $\delta(r - r_i)$ is the Dirac function. Numerical experiments show that parameterization $\sigma \phi$ is quite good in the case of such contaminants as CO, SO$_2$, Pb, C, etc. (Shir and Shich, 1974).

It is assumed that velocity $U(r, t)$ is known from observations or some dynamic model and satisfies the continuity equation

$$\text{div} U = 0$$

(3)

Eq. (1) is solved with the initial condition

$$\phi(r, 0) = \phi^0(r) \quad \text{at} \quad t = 0$$

(4)
Normally the pollution flux through the open boundary \( S \) of limited area \( D \) is unknown, and the errors made in determining the flux may propagate into the domain by advection and diffusion, perturbing or destroying the solution. Also, errors in the initial condition (4) and emission rates \( Q_i(t) \) can modify the solution. It is therefore important to put such boundary conditions, under which the problem will be posed correctly in a limited area, both physically and mathematically (Marchuk and Skiba, 1976; Marchuk, 1986).

For this purpose, we introduce the projection \( U_s = U \cdot n \) of velocity \( U \) on the unit external normal \( n \) to the boundary \( S \) of domain \( D \), and divide the whole boundary into the “inflow” part \( S^+ \) (where \( U_n < 0 \), and the pollution flux is directed inside \( D \)) and “outflow” part \( S^- \) (where \( U_n \geq 0 \), and the pollution flux is directed outside \( D \)) (Fig. 1).

Then we take the following boundary conditions:

\[
\begin{align*}
\mu \frac{\partial}{\partial n} \phi &= 0 \quad \text{at } S^+ \\
\mu \frac{\partial}{\partial n} \phi - U_n \phi &= 0 \quad \text{at } S^- 
\end{align*}
\]

(Marchuk and Skiba, 1976; Skiba, 1997). Skiba and Parra-Guevara (2000, 2011) showed that problem (1)-(5) is well posed according to Hadamard (1923), that is, it has a unique solution that continuously depends on the initial distribution \( \phi^0(r) \) and on the number \( N \), emission rates \( Q_i(t) \) and positions \( r \) of the industries.

One more integral equation is obtained if we multiply Eq. (1) by \( \phi(r, t) \) and integrate the result over \( D \):

\[
\frac{\partial}{\partial t} \int_D \phi^2 \, dr = 2 \sum_{i=1}^{N} Q_i(t) \phi(r, t) - 2 \int_D (\sigma \phi^2 + \mu |\nabla \phi|^2) \, dr - \int_{S^+} U_n \phi \, dS
\]

(Eq. 7)

Eqs. (6) and (7) mean that both the total concentration \( \int_D \phi \, dr \) and the solution norm \( ||\phi|| = (\int_D \phi^2 \, dr)^{1/2} \) increase under the influence of non-zero emission rates \( Q_i(t) \), and at the same time decrease due to dissipation (\( \sigma > 0 \), \( \mu > 0 \)) and advection pollution flux through the boundary \( S \) of domain \( D \). If \( f(r, t) \equiv 0 \) (emission rates are absent), and in addition, there is no dissipation (\( \sigma = 0 \), \( \mu = 0 \)) and \( U_n = 0 \) everywhere at boundary \( S \), then both integrals are invariable:

\[
\int_D \phi(t, r) \, dr = \text{const}, \quad ||\phi(t, r)|| = \text{const}
\]

Of course, these conservation laws are valid only under artificial conditions. Nevertheless these two laws and the balance Eqs. (6) and (7) are useful in testing numerical algorithms and computational programs (Skiba, 1997).

2.3 Description of sources in the models

The forcing \( f(r, t) \) of Eq. (1) depends on the nature of pollution source. In case of \( N \) industrial plants located in \( D \) (Fig. 2a), \( f(r, t) \) is defined by (2). And if the sources are distributed continuously along the main city roads \( R_i \), then

\[
f(r, t) = \begin{cases} Q_i(r, t), & \text{if } r \in R_i \\ 0, & \text{otherwise} \end{cases} \quad (i = 1, 2, ..., N)
\]

where \( Q_i(r, t) \) is the rate of emission of a pollutant along the road \( R_i \), \( i = 1, 2, ..., N \) (Skiba and Davydova-Belitskaya, 2003). Evidently, a superficially distributed source (e.g., in case of fire) can be described in like manner. However, as it is mentioned in Skiba and Davydova-Belitskaya (2003) and Parra-Guevara and Skiba (2003), the emission rates \( Q_i(r, t) \) continuously distributed along some line \( R_i \) (or superficially distributed over some area) can also be described in the discrete form (2) by dividing the line (or area) into small parts and discretizing the function \( Q_i(r, t) \) (Fig. 2b). This method was used by
Skiba and Davydova-Belitskaya (2003) to introduce in the model the vehicular sources located along the main roads in Guadalajara City. Figure 3 shows the distribution of carbon monoxide concentrations calculated with model (1)-(5) by using the climatic winds of dry season (a) and rainy season (b). One can see the importance of wind direction in the distribution of a pollutant.

3. Dual estimates

Figure 3 shows that by solving the problem (1)-(5) we can study the behavior of pollutant concentration in any point of domain $D \times (0, T)$. However, this is not an efficient way to answer the important question: To what extent this or that source is responsible for the contamination of a particular zone? It is much easier to answer the question with the adjoint approach,
widely used in the model sensitivity study and control theory (Marchuk and Orlov, 1961). The main advantage of this approach is the use of solutions of adjoint problems as valuable information functions (Lewins, 1965).

3.1 Adjoint dispersion model

The adjoint dispersion model in domain $$D$$ (Fig. 1) and time interval $$(0, T)$$ is constructed with the help of an operator that is adjoint to the operator of model (1)-(5). The adjoint operator is defined by means of Lagrange identity (Marchuk and Skiba, 1976; Marchuk, 1986), and the adjoint model accepts the form

$$\frac{\partial g}{\partial t} - \text{div}(Ug) + \sigma g - \text{div}(\mu \nabla g) = p(r, t)$$

in $$D \times (0, T)$$

$$g(r, T) = 0 \quad \text{in} \quad D$$

$$\mu \frac{\partial g}{\partial n} + U_{\text{as}} g = 0 \quad \text{at} \quad S'$$

$$\mu \frac{\partial g}{\partial n} = 0 \quad \text{at} \quad S^-$$

In Eq. (8) the wind velocity $$U(r, t)$$ and coefficients $$\mu(r, t)$$ and $$\sigma(r, t)$$ are the same as in Eq. (1). Let us compare the dispersion problem (1)-(5) with adjoint dispersion problem (8)-(10) in the case when $$f(r, t) \equiv 0$$ and $$p(r, t) \equiv 0$$. One can see that after using the substitution $$t' = T - t$$ in Eq. (10), it differs from Eq. (1) only in the sign of velocity $$U$$. As a result, the inflow part $$S^-$$ and outflow part $$S^+$$ of problems (1)-(5) and (8)-(10) are swapped. This fact explains why the boundary conditions (5) are replaced by the conditions (10). It also shows that the adjoint problem is well posed only if it is solved in the opposite time direction: from $$t = T$$ to $$t = 0$$ (Skiba and Parra-Guevara, 2000). That is why we take “initial” condition (9) at the moment $$t = T$$.

3.2 Duality principle

We now show how to define the forcing $$p(r, t)$$ of the adjoint problem and explain the importance of the adjoint solution $$g(r, t)$$. Suppose it is required to determine the mean concentration of pollutant $$\phi(r, t)$$ in some ecologically sensible zone $$\Omega \subset D$$ and time interval $$(T - \tau, T)$$. Let $$\omega(r, t)$$ be a positive function in domain $$\Omega \times (T - \tau, T)$$ such that

$$\int_{T-\tau}^T \int_{\Omega} \omega(r, t) \, dr \, dt = 1,$$

and hence, the integral

$$J_\omega(\phi) = \int_{T-\tau}^T \int_{\Omega} \omega(r, t) \phi(r, t) \, dr \, dt$$

represents an average concentration of pollutant $$\phi(r, t)$$ in space-time domain $$\Omega \times (T - \tau, T)$$.

We now subtract the Eq. (8) pre-multiplied by $$\phi(r, t)$$ from the Eq. (1) pre-multiplied by $$g(r, t)$$, and integrate the result over domain $$D \times (0, T)$$. The initial and boundary conditions (4)-(5) and (9)-(10) lead then to the duality principle (Marchuk and Skiba, 1976; Skiba and Parra-Guevara, 2011):

$$\int_{0}^{T} \int_{D} p(r, t) \phi(r, t) \, dr \, dt = \sum_{i=1}^{N} \int_{0}^{T} g(r, t) Q_i(t) \, dt + \int_{D} g(r, 0) \phi^0(r) \, dr$$

If forcing $$p(r, t)$$ in (8) is defined as

$$p(r, t) = \begin{cases} \omega(r, t), & \text{if } (r, t) \in \Omega \times (T - \tau, T) \\ 0, & \text{otherwise} \end{cases}$$

then the last equation leads to one more (equivalent) estimate of average concentration of contaminant $$\phi(r, t)$$ in zone $$\Omega$$ and interval $$(T - \tau, T)$$:

$$J_\omega(\phi) = \int_{T-\tau}^T \int_{\Omega} \omega(r, t) \phi(r, t) \, dr \, dt$$

$$= \sum_{i=1}^{N} \int_{0}^{T} g(r, t) Q_i(t) \, dt + \int_{D} g(r, 0) \phi^0(r) \, dr$$

In the particular case that $$\omega(r, t) = 1/(\tau |\Omega|)$$ in the domain $$\Omega \times (T - \tau, T)$$, where $$|\Omega|$$ is the area of $$\Omega$$, estimate (11) leads to the mean concentration of pollutant $$\phi(r, t)$$ in the space-time domain $$\Omega \times (T - \tau, T)$$:

$$J(\phi) = \frac{1}{\tau |\Omega|} \int_{T-\tau}^T \int_{\Omega} \phi(r, t) \, dr \, dt$$
(the so-called direct estimate). At the same time, Eq. (13) provides the equivalent (dual) adjoint estimate:

$$J(\phi) = \sum_{i=1}^{N} \int_0^T g(r_i, t)Q_i(t)dt + \int_D g(r, 0)\phi^0(r)d\mathbf{r}$$  \hspace{1cm} (15)

(Marchuk and Skiba, 1976). It means that forcing \(p(r, t)\) of adjoint problem (8)-(10) characterizes the average concentration \(J(\phi)\) of pollutant \(\phi(r, t)\) in \(\Omega \times (T - \tau, T)\). According to adjoint estimate (15), the concentration \(J(\phi)\) in zone \(\Omega\) explicitly depends on the emission rates \(Q_i(t)\) and initial distribution \(\phi^0(r)\) in \(D\), and adjoint solution \(g(r, t)\) serves as the weight function that determines the contribution of each source \(Q_i(t)\) and initial pollution level \(\phi^0(r)\) into the average concentration \(J(\phi)\) in \(\Omega\).

Note that the role of initial distribution of contaminant \(\phi^0(r)\) decreases when the interval \((0, T - \tau)\) increases (Skiba, 1993). Really, by (12), \(p(r, t) \equiv 0\) in \((0, T - \tau)\), and, due to the dissipation process \((\mu > 0, \sigma > 0)\), the weight function \(g(r, 0)\) in (19) decreases as \(T - \tau\) increases. If \(g(r, 0)\) is relatively small then (15) is reduced to

$$J(\phi) = \sum_{i=1}^{N} \int_0^T g(r_i, t)Q_i(t)dt$$  \hspace{1cm} (16)

3.3 Particular qualities of dual estimates

The direct estimate (14) and adjoint estimate (15) are equivalent and complement each other rather well in monitoring the current ecological state. Depending on the situation, one of these formulas may be preferable. The direct estimate (14) uses the solution \(\phi(r, t)\), and hence, the problem (1)-(5) must be solved again whenever the number \(N\) of sources, their positions \(\mathbf{r}\), or emission rates \(Q_i(t)\) vary. Of course, the direct evaluation should be used if the pollution concentration is estimated in each point, or in many zones of domain \(D\). However, such comprehensive information is rather costly and often unnecessary. In many cases it is sufficient to know value (14) only in a few ecologically most important zones of region \(D\). Then it is better to find the solutions \(g_i(r_i, t)\) of the adjoint model (8)-(10) for every zone and use the adjoint estimates (15). In some cases the estimates (15) give an immediate solution to non-trivial problems (Skiba et al., 2005; Dang et al., 2012). Also, the adjoint estimates are important to control the emission rates of pollution sources. In contrast to problem (1)-(5), the adjoint problem (8)-(10) is independent of the number of sources \(N\), their positions \(\mathbf{r}\), and emission rates \(Q_i(t)\), and therefore its solution can be found for each zone \(\Omega\) independently of specific values for all these parameters.

The adjoint method is especially useful when the dispersion problem is considered with time-independent (for example, climatic) parameters \(U(r), \mu(r)\) and \(\sigma(r)\) (Skiba and Davydova-Belitskaya, 2002). Then any solution to adjoint problem \(g(r, t)\), once calculated for a specific zone \(\Omega\), can be reused for different parameters \(N, r, Q_i(t)\) (Figs. 4-6). Moreover, the estimate (16) uses only the values \(g(r, t)\) in the positions \(r_i\) of sources, and therefore, there is no need to keep in a computer the values of adjoint solutions in all grid points.

3.4 Sensitivity of estimates

Suppose that the number \(K\) of zones \(\Omega_k \subset D (k = 1, ..., K)\) is much less than number \(N\) of pollution sources. Then the adjoint estimates (15) are very helpful and effective in studying the sensitivity of concentrations \(J_k(\phi)\) to variations in emission rates \(Q_i(t)\), positions \(r_i\) and number \(N\) of sources, as well

Fig. 4. Isolines of solution \(g(r, t)\) calculated for the Historical Center of Guadalajara City with climatic rainy season wind at \(t = T - 60\) min (dotted lines) and \(t = T - 90\) min (continuous lines); \(T = 360\) min.
as to variations in the initial distribution of contaminant $\phi^0(\mathbf{r})$.

Let us derive a few sensitivity formulas. Due to the linearity of problem (1)-(5), it is easy to obtain

$$
\delta J(\phi) = \sum_{i=1}^{N} \int_{t=0}^{T} g(\mathbf{r}_i, t) \delta Q_i(t) \, dt + \int_{\Omega} g(\mathbf{r}, 0) \delta \phi^0(\mathbf{r}) \, d\mathbf{r} \quad (17)
$$

where $\delta J(\phi)$ is a variation in the mean concentration (15) in zone $\Omega$ due to variations in $\phi^0(\mathbf{r})$, $Q_i(t)$ and/or $N$.

If $\mathbf{r}_i$ and $\mathbf{r}_i'$ are two different positions of sources in domain $D$ then the $\mathbf{r}_i$-dependence of average concentration $J(\phi)$ is given by

$$
\delta J(\phi) = \sum_{i=1}^{N} \int_{t=0}^{T} [g(\mathbf{r}'_i, t) - g(\mathbf{r}_i, t)] Q_i(t) \, dt \quad (18)
$$

All variations in (17) and (18) are arbitrary. We now obtain a general formula for analyzing the sensitivity of $J(\phi)$ with respect to small variations of model parameters. In addition to solution $\phi$ to problem (1)-(5), we also consider the solution $\tilde{\phi} = \phi + \phi'$ to perturbed problem

$$
\frac{\partial}{\partial t} \tilde{\phi} + (\mathbf{U} + \mathbf{U}') \cdot \nabla \tilde{\phi} + (\sigma + \sigma') \tilde{\phi} - \nabla \cdot \left[ (\mu + \mu') \nabla \tilde{\phi} \right] = f + f' 
$$

$$
\tilde{\phi}(\mathbf{r}, 0) = \phi^0(\mathbf{r}) + \delta \phi^0(\mathbf{r}) \quad \text{in } D
$$

$$
\mu \frac{\partial}{\partial n} \tilde{\phi} - U_n \tilde{\phi} = 0 \quad \text{at } S^-, \quad \mu \frac{\partial}{\partial n} \tilde{\phi} = 0 \quad \text{at } S^+
$$

where

$$
f'(\mathbf{r}, t) = \sum_{i=1}^{N} \delta Q_i(t) \delta (\mathbf{r} - \mathbf{r}_i) + \sum_{i=1}^{N} \delta Q_i(t) \delta (\mathbf{r} - [\mathbf{r}_i + \delta \mathbf{r}_i])
$$
To simplify the study, we assume here that $U'$ and $\mu'$ are reduced to zero at the boundary $S$ and all the perturbations $U'$, $\phi'$, $\mu'$, $\sigma'$, $\delta \phi$, and $\delta r$ are rather small. Then we can apply the adjoint method to the linearized equation

$$
\frac{\partial}{\partial t} \phi' + U \cdot \nabla \phi' + \alpha \phi' - \nabla \cdot [\mu \nabla \phi'] = f' - U' \cdot \nabla \phi - \sigma' \phi + \nabla \cdot [\mu' \nabla \phi']
$$

for perturbations $\phi'$ and get

$$
\delta J (\phi) = \sum_{i=1}^{N} \int_0^T g(r_i, t) \delta Q_i(t) dt + \int_D g(r, 0) \delta \phi^0 (r) dr
$$

$$
+ \sum_{i=1}^{N} \int [\nabla g(r_i, t) \cdot \delta r_i] Q_i(t) dt
$$

$$
- \int_D g \left[ U' \cdot \nabla \phi + \sigma' \phi - \nabla \cdot [\mu' \nabla \phi] \right] dr dt
$$

The last two terms of the right-hand side of (19) demonstrate the contribution of small perturbations $U'$, $\mu'$, $\sigma'$, $\delta r_i$ to variation $\delta J (\phi)$ of mean concentration $J (\phi)$ in zone $\Omega$. It should be noted that in contrast to estimates (17) and (18), the last term in (19) already contains the solution $\phi(r, t)$ of non-perturbed problem (1)-(5). Thus, solution $\phi(r, t)$ is not used only if $U' = \sigma' = \mu' = 0$ everywhere in $D$. Then only the adjoint problem (8)-(10) must be solved.

4. Three simple strategies for pollution control

Let us formulate the problem of control of emission rates. Suppose that we have a model $\mathcal{M}$ that predicts the dispersion of a pollutant $\phi$ in a limited area $D \subset \mathbb{R}^m$ ($m = 2, 3$) and time interval $(0, T)$:

$$
\mathcal{M} : \widetilde{\mathcal{Q}} \mapsto \phi, \quad \widehat{\mathcal{Q}} (t) = (Q_1(t), Q_2(t), ..., Q_N(t))
$$

where $Q_i(t) \geq 0$ is the rate of emission of contaminant $\phi$ of the $i$th source located at $r_i \in D$ ($i = 1, 2, ..., N$). In particular, (1)-(5) can be taken as such a model. Let the functional (14) be used as the mean concentration $J (\phi)$ of pollutant $\phi$ in a zone $\Omega \subset D$ and time interval $[T - \tau, T]$, and let $J_0$ be a sanitary norm admissible for the pollutant $\phi$. If the model $\mathcal{M}$ gives an unfavorable forecast of air quality, that is, the mean concentration exceeds the sanitary norm: $J (\phi) > J_0$, then the emission rates $\widehat{\mathcal{Q}}(t)$ were excessive, and must be reduced in interval $(0, T)$. The idea is to determine such reduced values $\bar{Q}^i(t) \leq \widehat{Q}(t)$ in order to prevent high levels of pollutant $\phi$ in time-space domain $\Omega \times [T - \tau, T]$. It means that the re-forecast with the reduced emission rates $\bar{Q}(t)$ will give the satisfactory result: $J (\phi) \leq J_0$.

This inverse problem may have many solutions or none, depending on the initial distribution of pollutant $\phi(0)$ in domain $D$ (Parra-Guevara and Skiba, 2003, 2006). So it is an ill-posed problem. In order to get a well-posed problem, one should apply a regularization method that in a sense represents a control strategy. Let us consider three simple examples.

4.1 Strategy 1: Control of total mass of emitted pollutant

This control strategy can be defined as the following optimization problem:

$$
\min F (\bar{Q}) = \sum_{i=1}^{N} \left\| Q_i \right\|^2, \text{ subject to } J (\phi) \leq J_0
$$

where $\left\| Q_i \right\| = \sqrt{\int_0^T Q_i^2 (t) dt}$. Thus, $F (\bar{Q})$ represents the total mass of pollutant $\phi$ emitted within interval $[0, T]$ by $N$ sources located at points $r_i$ with emission rates $Q_i(t)$. The solution of problem (20) is

$$
Q_i^* = \gamma_i \alpha \frac{g(r_i, t)}{\|g(r_i, t)\|}^2, \quad i = 1, ..., N,
$$

(Parra-Guevara and Skiba, 2000a; Parra-Guevara, 2001) where $\gamma_1 + \gamma_2 + \cdots + \gamma_N = 1$, $\gamma_i = m_i / (\sum_{j=1}^{N} m_j)$, and

$$
Q_i^* = \gamma_i \alpha \frac{g(r_i, t)}{\|g(r_i, t)\|}^2, \quad i = 1, ..., N,
$$

(Parra-Guevara and Skiba, 2000a; Parra-Guevara, 2001) where $\gamma_1 + \gamma_2 + \cdots + \gamma_N = 1$, $\gamma_i = m_i / (\sum_{j=1}^{N} m_j)$ is the quota of the total mass of pollutant, emitted by the $i$th source when it works at full capacity ($i = 1, ..., N$), and

$$
\alpha = J_0 - \int_D g(r, 0) \phi^0 (r) dr.
$$

4.2 Strategy 2: Control of temporal behavior of emission rates

It should be noted that the control strategy (21) has the disadvantage that it may require stopping the sources for some time for the reason that the emission rates are proportional to the adjoint function $g(r, t)$, which can be equal to zero. Let us consider a new strategy of control that limits the behavior of emission rates in $(0, T)$, but does not require stopping the activity of sources when the adjoint solution $g(r, t)$ reduces to zero.
Again, we should find such $Q_i^* \in L_2(0, T)$ that $J(\phi) \leq J_0$. The idea is that intensity $Q_i^*(t)$ of the $i$th source may be high while $g(r_i, t)$ is small, and $Q_i^*(t)$ must be low while $g(r_i, t)$ is large. The advantage of this approach is that, in some periods of time (for example, when $g(r_i, t) = 0$), the corresponding source will be allowed to operate at full capacity (Parra-Guevara and Skiba, 2000a, 2003; Parra-Guevara, 2001). Let us define auxiliary functions

$$G_i(t) = \begin{cases} \alpha (|I_i| \cdot g(r_i, t))^{-1}, & \text{if } t \in I_i, \\ \delta_i, & \text{if } t \in [0, T] \setminus I_i \end{cases}, \quad (i = 1, \ldots, N)$$

where $I_i = \{ t \in [0, T] : g(r_i, t) > 0 \}$ and $|I_i|$ denotes its longitude, $\delta_i$ is the maximum emission rate corresponding to the $i$th source, and $[0, T] \setminus I_i$ is the complement of set $I_i$ to set $[0, T]$. Then the solution is $Q_i^*(t) \leq \gamma_i \cdot \min \{ \delta_i, G_i(t) \}$ for each $t \in [0, T]$ and $i = 1, \ldots, N$.

4.3 Strategy 3: Optimal time-independent emission rates

Suppose that $Q_i$ is the maximum possible emission rate of $i$th source located at $r_i$ and

$$a_i = \int_0^T g(r_i, t) \, dt > 0, \quad (i = 1, \ldots, N).$$

Assume that all sources operate at full capacity with power that results in the violation of the sanitary norm: $J(\phi) > J_0$ (and (15) and (22), this means that $\alpha < \sum_{i=1}^N a_i Q_i$). To prevent the excessive pollution of the zone, some emission rates must be reduced. We now find the maximum possible time-invariant emission rates $Q_i^* \leq Q_i$ which minimize the values $Q_i - Q_i^*$, do not lead to violation of the sanitary norm, giving the optimal result: $J(\phi) = J_0$, that is,

$$\sum_{i=1}^N a_i Q_i^* = \alpha.$$

Let us reformulate this strategy as the optimization problem

$$\min F(\bar{Q}^*) = \sum_{i=1}^N \frac{1}{\gamma_i} (Q_i - Q_i^*)^2$$

subject to $\sum_{i=1}^N a_i Q_i^* = \alpha$.

With Lagrange multipliers we obtain

$$\lambda = 2 \left( \frac{\alpha - \sum_{i=1}^N a_i Q_i}{\sum_{i=1}^N a_i^2 \gamma_i} \right),$$

$$Q_i^* = Q_i + 0.5 \lambda a_i \gamma_i, \quad i = 1, \ldots, N.$$  

(Parra-Guevara and Skiba, 2000a; Parra-Guevara, 2001). Obviously, $Q_i^* \leq Q_i$ for all $i$, since $\lambda < 0$, besides $Q_i^* \approx Q_i$ for small $\gamma_i$. Thus, this control results in limiting the emissions from the sources for which the corresponding values $a_i$ are large.

5. General strategy of optimal control

Let

$$F(q) = \| \tilde{Q} - q \|^2 = \sum_{i=1}^N \| Q_i - q_i \|^2_{L^2(0, T)}$$

be a functional defined in the domain

$$\Theta = \{ q_i(t) \in L_2([0, T]) : q_i(t) \geq 0, \quad (i = 1, \ldots, N) \} \quad J(\phi_q) \leq J_0 \}.$$  

Thus $\Theta$ is the set of such emission rates $\bar{q}(t)$ that guarantee the compliance with the sanitary standard in a zone $\Omega$: $J(\phi) \leq J_0$. The optimal control consists in finding such rates $\tilde{Q}^*(t) \in \Theta$ that minimize the functional $F(q)$ in $\Theta$:

$$F(\tilde{Q}^*) = \inf_{q \in \Theta} F(q).$$  

(Parra-Guevara and Skiba, 2000a; Parra-Guevara, 2001; Skiba and Parra-Guevara, 2011). Clearly, the control depends on the norm $\| \cdot \|$ used, and $\tilde{Q}^*(t)$ is the optimal solution that represents the least restriction on the sources. This variational problem is generally solved with an iterative optimization method using successive evaluation of the dynamic model $M$ (Elbern and Schmidt, 1999; Robertson and Langer, 1998). As a general rule, this process is not very efficient because it requires many calculations due to the complexity of model $M$. Therefore we will now describe another method based on using the adjoint operator and adjoint model, which allows us to solve the problem of optimal control without consistent estimation of model $M$. 

Note that the solution of problem (26) depends critically on the parameter \( \alpha \) defined by (22). Indeed, for \( \alpha < 0 \) there is no solution to (26) because the standard of health does not hold even if all emissions are reduced to zero (that is, any production activity is stopped). The following three results in this section were proved in Parra-Guevara and Skiba (2006, 2007).

**Theorem 1**
Let \( \alpha = 0 \). Then the optimal control problem (26) has only one solution:

\[
Q_i^*(t) = \begin{cases} 
0 & \text{if } t \in I_i \\
Q_i(t) & \text{if } t \in [0, T] \setminus I_i 
\end{cases}
\]

where \( I_i = \{ t \in [0, T] \mid g(r_i, t) > 0 \} \).

**Theorem 2**
If \( \alpha > 0 \) then the optimal control problem (26) has the unique solution \( \tilde{Q}^* \in \Theta \) such that \( Q_i^*(t) \leq Q_i(t) \) \((0 \leq t \leq T, 1 \leq i \leq N)\) and \( J(\phi) = J_0 \).

If there is only one source, the statement of Theorem 2 can be refined:

**Theorem 3**
Suppose that there is only one source with emission rate \( Q(t) \) located at the point \( r_0 \). If \( \alpha > 0 \) and \( J(\phi) > J_0 \) then

\[
\tilde{Q}^* = Q(t) - \beta g(r_0, t),
\]

\[
\beta = (J(\phi) - J_0) \int_0^T g(r_0, t) dt
\]

is the only solution for the problem of optimal control (26), on condition that it is a nonnegative function in \([0, T]\).

In connection with Theorem 2, the set of potential solutions (25) is reduced to

\[
\Theta = \left\{ q_i(t) \in L_2[0, T] ; \ q_i(t) \geq 0 , \ (i = 1, ..., N) \right\}
\]

\[
\sum_{i=1}^N \int_0^T g(r_i, t) q_i(t) dt = \alpha
\]

An approximate (numerical) solution to the problem of optimal control can be obtained with highly effective numerical algorithm of sequential orthogonal projections (Parra-Guevara and Skiba, 2006).

From the computational viewpoint, the new set (28) is much smaller than (25), and therefore preferable in calculations.

### 5.1 Strategies of control based on convex linear combinations

A new strategy to control emissions can always be developed with a convex linear combination of the existing strategies. Let \( K \) be a number of previously defined control strategies, besides, each strategy ensures compliance with the health standard in a zone \( \Omega : J(\phi) \leq J_0 \). Let \( \xi_1, \xi_2, ..., \xi_K \) be positive constants such that \( \xi_1 + \xi_2 + ... + \xi_K = 1 \), and let \( Q_{i,k}^* \) be a sufficient (or optimal) emission rate found by means of the \( k \)th control strategy for the \( i \)th source \((i = 1, ..., N, k = 1, ..., K)\).

Then the emission rates

\[
q_i^*(t) = \sum_{k=1}^K \xi_k Q_{i,k}^*(t), \quad i = 1, ..., N
\]

represent a new sufficient (non-optimal) strategy that also guarantees compliance with the health standard in the zone \( \Omega : J(\phi) \leq J_0 \).

### 6. Control of the source that emits lead particles

To illustrate the developed methods we now consider two examples in which the source emits the lead particles.

**Example 1.** Let \( D = (0, 2 \ \text{km}) \times (0, 2 \ \text{km}) \) be a square domain, while the single point source, located at \( r_0 = (1.8, 0.2) \), emits lead particles with emission rate \( Q = 3.8 \ \text{kg/h} \). For simplicity, we neglect the initial distribution of lead: \( \phi_0(r) = 0 \) in \( D \). The coefficients of deposition and diffusion are \( \sigma = 0.001 \ \text{h}^{-1} \) and \( \mu = 0.04 \ \text{km}^2\text{h}^{-1} \), respectively. The non-divergent wind velocity \( U = (u, v) \) is defined by the stream function \( \psi = xy \):

\[
u = -\psi_y = -x , \quad \nu = \psi_x = y
\]

The dispersion model (1)-(5) and adjoint model (8)-(10) are considered in the four-hour interval \((0, T)\). We will monitor the mean lead concentration \( J(\phi) \) in the zone \( \Omega = [0, 0.5] \times [0.5, 1.0] \) during the whole interval \((0, T)\), that is \((\tau = 4 \ \text{h})\). The sanitary norm is \( J_0 = 1.5 \ \mu g \text{ m}^{-3} \) (Seinfeld, 1992).

Isolines of the concentration of lead at intervals of one hour are presented in Figure 7, while isolines
of the solution $g(r, t)$ of adjoint model (8)-(10) are given in Figure 8. Figure 7 shows a clear increase in the concentration of lead when the direction of the wind is changed from southeast to northwest. Figure 8 demonstrates that during the four-hour interval (from $t = 4$ to $t = 0$), the step function $p(r, t)$ shifts in the direction of vector $-\mathbf{U}$ (that is, from north-west to south-east), as it should. The mean concentration of lead $J(\phi)$ calculated in zone $\Omega$ with emission rate $Q$ is 2.11 mg m$^{-3}$. The result is unsatisfactory ($J(\phi) > J_0$), and we will apply and compare five different control strategies: the control strategies (21), (23) and (24) with emission rates $Q_i^*$ ($i = 1, 2, 3$) and two control strategies defined with the convex linear combinations $Q_4^* = 0.3 \cdot Q_1^* + 0.7 \cdot Q_3^*$ and $Q_5^* = 0.5 \cdot Q_2^* + 0.5 \cdot Q_3^*$.

The mean lead concentrations obtained in zone $\Omega$ when the model (1)-(5) is solved with emission rates $Q_i^*(t)$, prescribed by the five control strategies ($i = 1, ..., 5$), are shown in Table I, while Figure 9 shows the temporal behavior of $Q_i^*(t)$.

All five control strategies correspond to the level of health, and provide an alternative to the original source intensity $Q$. However, the emission rate $Q_3^*$ (optimal control), as well as the rates $Q_2^*$ and $Q_4^*$ (convex control) are the most preferred as they require less drastic changes in the intensity of the original source. Although the emission rate $Q_2^*$ is only 40% of the original rate $Q$ in the first half of the time, it coincides with the original rate $Q$ during the second half of the time, and this fact can also be attractive.

Note that, like the original rate $Q$, the optimal emission rate $Q_3$ is stationary (it is 71% of $Q$). This makes $Q_3$ a simple alternative to the original industrial source activity. The results show that among the five strategies, the first strategy with emission rate $Q_1$ has the most serious consequences for the industrial plant activity, because it requires the work stoppage during 25% of the total time.

Example 2. In this example domain $D$ and wind velocity $U$ are the same as in Example 1. Moreover, the source also emits lead particles and is located at the same place. However, we now consider the four different original emission rates of the source:

\[
Q_1(t) = 3.8, \quad Q_2(t) = \begin{cases} 
4, & 0 \leq t < 1 \\
5 - t, & 1 \leq t \leq 4 
\end{cases}, \\
Q_3(t) = \cos \pi t + 3.5, \quad Q_4(t) = \begin{cases} 
3, & 0 \leq t < 1 \\
\frac{2}{3}(t-1)+3, & 1 \leq t \leq 4 
\end{cases}
\]
Thus, rate $Q_1$ is constant, rate $Q_2$ is invariable during the first hour and then linearly decreases, rate $Q_3$ is a periodic function with a two-hour period, and rate $Q_4$ is invariable during the first hour and then linearly increases. The mean lead concentrations $J(\phi)$ calculated in zone $\Omega$ with each emission rate $Q_i$ ($i = 1, \ldots, 4$) are $2.11 \, \mu g \, m^{-3}$, $2.02 \, \mu g \, m^{-3}$, $1.97 \, \mu g \, m^{-3}$ and $1.81 \, \mu g \, m^{-3}$, respectively. In other words, all the results are unsatisfactory ($J(\phi) > J_0$ for any $i$, where $J_0 = 1.5 \, \mu g \, m^{-3}$). In order to prevent the violation of sanitary standards, we apply in all four cases the optimal control method (27). Figure 10 shows both the original emission rates $Q_i(t)$ and the optimal emission rates $q_{opt}(t)$ given by the control. As it should be, for each $i$, the mean lead concentration $J(\phi)$ obtained with the optimal emission rate $q_{opt}(t)$ coincides with norm $J_0 = 1.5 \, \mu g \, m^{-3}$.

Table I. Mean lead concentrations $J(\phi)$ in $\Omega$.

In complete agreement with the theory, $q_{opt}(t) \leq Q_i(t)$ for all $t \in (0, 4)$ and $1 \leq i \leq 4$. Moreover, Figure 10 shows that for each $i$, $q_{opt}(t) = Q_i(t)$ during the last hour ($3 \leq t \leq 4$). It means that the optimal and original emission rates coincide to each other during the time interval when the value $g(r_1, t)$ of the adjoint model solution is equal to zero, and due to (15), the source emissions do not contribute to the pollution of zone $\Omega$. At last, it is interesting to note that in the interval $0 \leq t < 3$, in which these values do not match, the temporal behavior of the optimal emission rate $q_{opt}(t)$ is similar to the time behavior of the corresponding original rate $Q_i(t)$ ($i = 1, \ldots, 4$). This result is useful because it means that the optimal strategy (27) does not require radical changes in the operation of an industrial enterprise.

7. Cleaning of polluted aquatic zones

The above-mentioned control methods have been illustrated with simple examples using two-dimensional dispersion models. However, these methods can also be applied to three-dimensional dispersion models. We will consider now a three-dimensional dispersion model for expanding the application scope of pollution control methods to the cleaning of some aquatic zones contaminated with biofilm (remediation) or oil (bioremediation). In these problems,
Fig. 9. Emission rates obtained with five control strategies (the asterisks in $Q_i(t)$ are omitted).

Fig. 10. Temporal behavior of original emission rates $Q_i(t)$ and optimal emission rates $q_{opt}(t)$ in four experiments.
Control of emission rates

7.1 Dispersion model
The concentration of a chemical substance (hereinafter the cleaner) \( \phi(r,t) = \phi(x,y,z,t) \) in a domain \( D \subset \mathbb{R}^3 \) (Fig. 11) and time interval \( (0, T) \) is estimated with a 3D dispersion model (Skiba and Parra-Guevara, 2011):

\[
\frac{\partial \phi}{\partial t} + U \cdot \nabla \phi - \mu \nabla \cdot \phi = Q(t) \delta(r-r_0) \\
\phi_s = -v_s \phi \nabla \cdot \bar{k} \quad \text{in } D \\
\mu \frac{\partial \phi}{\partial n} = \phi_s \cdot \bar{n} - \zeta \phi \nabla \cdot \bar{k} \cdot \bar{n} \quad \text{at } S_r \\
\mu \frac{\partial \phi}{\partial n} = 0 \quad \text{at } S^+ \\
\mu \frac{\partial \phi}{\partial n} = -U_n \phi = 0 \quad \text{at } S^- \\
\mu \frac{\partial \phi}{\partial n} = 0 \quad \text{at } S_g \\
\phi(r,0) \equiv \phi^0(r) \quad \text{in } D \\
\nabla \cdot U = 0 \quad \text{in } D
\]

(29) \quad (30) \quad (31) \quad (32) \quad (33) \quad (34) \quad (35) \quad (36)

Here \( U = \bar{U}(r,t) \) is the current velocity that satisfies the continuity equation (36), and \( \mu(r,t) \) is the turbulent diffusion coefficient. In (29), the term \( \sigma \phi \) parameters the decay of a cleaner in the water due to various physical and chemical processes, term \( \nabla \cdot \phi_s \) describes the process of sedimentation of the cleaner with constant velocity \( v_s > 0 \), and \( \delta(r-r_0) \) is the Dirac delta centered in the point of discharge of cleaner \( r_0 \). Eq. (31) is the boundary condition at free surface \( S_r \), where coefficient \( \zeta(r,t) \) characterizes the process of evaporation of cleaner, and (34) represents the boundary condition at bottom \( S_g \) of domain \( D \). The boundary conditions (32) and (33) at the lateral surface are identical to conditions (5), and (35) represents the initial distribution of the cleaner at \( t = 0 \). Note that \( \bar{n} \) is the unit outer normal to the boundary \( \partial D = S_r \cup S^+ \cup S^- \cup S_g \) of domain \( D \), and \( \bar{k} = (0,0,1)' \) is the unit vector directed upwards in the Cartesian coordinate system, besides,

\[
\bar{k} \cdot \bar{n} = 0 \quad \text{at } S^+ \cup S^-, \quad \text{and} \\
\bar{U} \cdot \bar{n} = 0 \quad \text{at } S_r \cup S_g
\]

(37)

Also note that conditions (31)-(34) take into account the topography and free surface of arbitrary form.

It is shown in Skiba and Parra-Guevara (2011) that the three-dimensional problem (29)-(36) is well posed, that is, its solution exists, is unique and stable to perturbations in forcing and initial condition

\[
\| \phi \|_{L^\infty(0,T)} \leq T \max_{0 \leq t \leq T} \| Q(t) \delta(r-r_0) \| + \| \phi^0(r) \|,
\]

(38)

and satisfies the mass balance equation

\[
\frac{\partial}{\partial t} \int_D \phi \, dr = Q(t) - \int_D \sigma \phi \, dr - \int_{S_r} U_n \phi \, dS \\
- \int_{S_g} \zeta \phi \bar{k} \cdot \bar{n} \, dS + \int_{S^+} v_s \phi \bar{k} \cdot \bar{n} \, dS
\]

(39)

Since \( \bar{k} \cdot \bar{n} > 0 \) at \( S_r \) and \( \bar{k} \cdot \bar{n} < 0 \) at \( S_g \), the total mass of the cleaner increases due to the discharge rate \( Q(t) \) and decreases due to the chemical transformation, advective flow through \( S^+ \), evaporation and sedimentation.

7.2 Optimal control of discharge rates
Assume now that there are \( N \) polluted zones \( \Omega_i \) \( (i = 1,\ldots,N) \) in an aquatic system (domain \( D \)), and we should purify them with the help of a chemical agent (Parra-Guevara and Skiba, 2007). Being released at a point \( r_0 \in D \) (Fig.12), the chemical substance spreads due to advection and diffusion, and while reaching the zones \( \Omega_i \), purifies polluted water. The goal is to find an optimal position of the source \( r_0 \), in sense that the emission of the cleaning agent in such a point will minimize its consumption (that is, will generate

Fig. 11. View of the domain \( D \) from above.
in the zones \( \Omega_i \) the minimum concentrations of the cleaning agent necessary for water purification. In a case where the contaminant is fairly stable (biofilm), the critical concentration \( J_i \) of an antimicrobial agent (chlorine, iodine, etc.) must be maintained in each zone \( \Omega_i \) for a long time interval \((T - \tau, T)\).

In other words, we have to determine the discharge point \( r_0 \) and the emission rate \( Q \), which meet the following constraints:

\[
J_i(\phi) = \bar{J}_i \quad i = 1, \ldots, N
\]

where \( \phi(r, t) \) is the concentration of a chemical agent determined by the model (29)-(36) with the initial condition \( \phi(0, t) = 0 \), and \( J(\phi) \) is its mean concentration (14) in \( \Omega_i \). Furthermore, not to damage the ecology of the environment, one should minimize the total mass \( F(Q) \) of the chemical agent discharged into the water. In this connection, the optimal control problem is posed as follows:

\[
\text{minimize} \quad F(Q) = \sqrt{\int_0^t \mathcal{Q}^2(t) \, dt}
\]

subject to: \( J_i(\phi) = \bar{J}_i, i = 1, \ldots, N \), \( 0 \leq t \leq T \)

The analytical and numerical solutions of this problem were obtained in Parra-Guevara and Skiba (2011):

\[
\mathcal{Q}^* = \frac{1}{\det(\Psi(r_0))} \sum_{j=1}^N \det(\Psi_j(r_0)) \bar{J}_j \]

where \( \Psi = \{\psi_j\} \) is the Gram matrix of order \( N \) whose entries

\[
\psi_j = \int_0^t g_i(r_0, t) g_j(r_0, t) \, dt
\]

are the inner products of adjoint functions, and matrix \( \Psi_i \) is obtained from \( \Psi \) by replacing its \( i \)th column with the corresponding components of the vector of critical concentrations \( J = (J_1, \ldots, J_N)^T \). Then the optimal discharge point \( r_0 \) is found while minimizing the functional.

**Example 3.** With the aim to demonstrate the skill of the method, we now consider a simple example of remediation in a three-dimensional channel 120 m long \([0, 120]\), 10 m wide \([0, 10]\), and 4 m deep \([0, 4]\), \( H = 4 \). The following three zones \( \Omega_i \) contaminated by biofilms (\( N = 3 \)) are considered:

\[
\Omega_1 = [20, 30] \times [9, 10] \times [0, 4],
\]

\[
\Omega_2 = [70, 80] \times [9, 10] \times [0, 4],
\]

\[
\Omega_3 = [95, 100] \times [0, 2] \times [0, 4].
\]

The critical concentrations of the cleaning agent \( c_i (gm^{-3}) \) in the zones vary from one experiment to another (Table II) and generate different optimal discharge rates \( Q^*_k \) (Fig. 13). The parameters of the three-dimensional adjoint model are taken as follows: the velocity vector \( \vec{U} \) is horizontally directed along the channel and is equal to 30 \( m^2 h^{-1} \), \( \vec{I} = (1, 0, 0)^T \), \( \mu = 6 \, m^2 h^{-1} \), \( \sigma = 1 \, h^{-1} \), and the processes of evaporation and sedimentation are neglected. The cleaner (chlorine) is discharged at the point \( r_0 = (3, 2.2, 2) \) during

Control of emission rates

the total time interval of $4 \text{ h}: (0, 7) \equiv (0, 4)$, and the mean concentration is controlled within the last one-hour interval $(3, 4)$, i.e., $\tau = 1 \text{ h}$.

The adjoint functions $g_i(\bar{r}_0, t)$ for the three zones ($i = 1, 2, 3$) are given in Figure 14. For the 7th experiment, the evolution of mean chlorine concentration in zones $\Omega_i$ ($i = 1, 2, 3$) is shown in Figure 15, while isolines of the mean chlorine concentration in domain $D$ at the final moment $T = 4 \text{ h}$ are presented in Figure 16. The optimal discharge rate applied is

![Fig. 13. Optimal discharge rates $q_k(t) = Q_k(t) / H$, $k = 1, 2, \ldots, 7$.](image)

![Fig. 14. Adjoint functions $g_i(\bar{r}_0, t)$, $i = 1, 2, 3$.](image)
In all experiments, the optimal discharge rate was successfully found with (40).

8. Conclusions
In this work, the fluid dynamics is assumed to be known, and the problem of dispersion of contaminants, governed by the advection-diffusion equation, is considered separately from the fluid dynamics. A few methods are suggested for estimating the mean concentration of pollutants in ecologically sensitive zones and preventing their dangerous levels through a control of emission rates of sources. The methods use the adjoint approach and equivalent direct and adjoint estimates of pollution concentration in specific zones. We use the fact that the adjoint estimates depend explicitly on the number, positions and emission rates of the sources and the initial distribution of pollutants in the region, and the solutions of adjoint problems serve in such estimates as weight function providing valuable information on the contribution of each source and initial data into the pollution of the zone. These properties make the adjoint estimates efficient for studying the model response to variations in the emission rates and initial conditions, and for developing control strategies.

Both non-optimal (sufficient) and optimal control strategies have been developed. The objective of each control strategy consists in preventing the violation of existing sanitary standards by means of reducing the emission rates of sources. Each control strategy
is designed by using the pollution dispersion model, its adjoint model, and taking into account the number of sources to control, their locations, initial distribution of pollutant in the domain, and corresponding sanitary standards. The methods are illustrated by simple examples. The methods developed for the air-quality control are also applied for cleaning a few aquatic zones polluted with biofilm (remediation) or oil (bioremediation).

Acknowledgements
The authors are grateful to Dr. V. Davydova-Belitskaya for providing some figures. This work was partially supported by the projects PAPIIT IN104811-3 and PAPIIT IN103313-2 (UNAM, México) and by the grants 14539 and 25170 of Sistema Nacional de Investigadores (Conacyt, Mexico).
